Key Points:

- Buoyancy anomalies generated by ocean mixed layer eddies can be diagnosed through spatial filtering of sea surface height.
- Sea surface height gradient can be used to parameterize the vertical eddy buoyancy flux in the mixed layer.
- Mixed layer depth and vertical heat flux can be estimated from surface-observable quantities.

Corresponding author: Abigail Bodner, abodner@mit.edu

Abstract

Submesoscale dynamics strongly influence the upper ocean, regulating mixing, air–sea exchange, and vertical heat transport. The recent SWOT mission provides unprecedented high-resolution observations of sea surface height (SSH), yet linking these surface measurements to subsurface ocean dynamics remains challenging. We develop a theoretical framework for diagnosing key mixed layer properties from surface-observable states. We show that horizontal density anomalies induced by mixed-layer eddies produce surface imprints that can be effectively captured by spatially filtered SSH. The filtered SSH is integrated into the Mixed Layer Eddy parameterization to infer the effects of submesoscale restratification. A potential energy budget accounting for the mixing-restratification competition in the mixed layer is diagnosed from surface buoyancy flux, wind stress, and the SSH gradient, enabling reconstruction of the mixed-layer depth. Vertical eddy heat flux can be further reconstructed from the SSH gradient. This framework offers a promising approach for diagnosing interior submesoscale processes using surface observations.

Plain Language Summary

Ocean submesoscale flows, occurring at scales of roughly 1–30 km, are crucial for moving heat, carbon, and other materials vertically in the upper ocean. These flows affect how the ocean mixes and how it exchanges heat and gases with the atmosphere. Because direct observations are difficult and expensive, much of the subsurface ocean remains largely unexplored. The recently launched Surface Water and Ocean Topography (SWOT) satellite provides exceptionally detailed measurements of sea surface height. However, it is still challenging to use these observations to understand what is happening beneath the ocean’s surface. This study reduced the gap by developing a theoretical framework that uses surface information to reveal important details about the subsurface, such as how deep the mixed layer is and how heat moves up and down. Submesoscale mixed-layer eddies—swirling motions in the well-mixed surface layer—are known to generate signals that can be detected from variations in sea surface height. By applying a spatial filter to remove large-scale signals, the surface signals created by these eddies can be used to reconstruct mixed layer depth and vertical heat flux. This method provides a practical way to estimate subsurface changes from surface states and can be applied to future observations.

1 Introduction

Submesoscale dynamics in the ocean mixed layer (ML) play a crucial role in regulating global heat and carbon uptake (Su et al., 2018; Guo et al., 2024), primary productivity (Mahadevan, 2016), and energy transfer (Taylor & Thompson, 2023; Srinivasan et al., 2023; Buckingham et al., 2019). Submesoscale fronts, characterized by strong horizontal density gradients, are typically driven by large-scale convergent flow (McWilliams, 2019; Yu et al., 2024). These fronts are often susceptible to baroclinic instability (Boccaletti et al., 2007), which gives rise to submesoscale eddies in the ML. Through slumping denser water beneath lighter water, the submesoscale eddies tilt isopycnals and act to restratify the ML (Fox-Kemper et al., 2008; Fox-Kemper & Ferrari, 2008). In addition, observations indicate that submesoscale eddies contribute substantially to upward vertical heat transport (Torres et al., 2025; Siegelman et al., 2020).

However, the dynamics and impacts of ML eddies are not fully understood. Despite the importance of submesoscale processes in the ML, fully resolving them requires a very high model resolution (Taylor & Thompson, 2023), resulting in substantial computational cost that limits both the duration and horizontal extent of numerical simulations. Moreover, although satellite observations (*e.g.*, sea surface temperature and salinity) and *in situ* measurements (*e.g.*, regional field campaigns and autonomous underwater vehicles) provide valuable insights into upper-ocean variability, their limited spatial

and temporal coverage hinders a comprehensive dynamical understanding of ML processes. The recent launch of the Surface Water and Ocean Topography (SWOT) satellite now enables global observations of high-resolution sea surface height (SSH), revealing ubiquitous submesoscale variability (Archer et al., 2025; X. Zhang & Callies, 2025; Z. Zhang et al., 2024). However, a critical gap remains in linking satellite observations to subsurface dynamics, in spite of recent efforts based on idealized theoretical models such as the surface quasi-geostrophic theory (Carli et al., 2024; Dù et al., 2025; Y. Zhang et al., 2025). Closing this gap would enable global diagnosis of ML processes from surface observations, which would be extremely valuable.

In this study, we develop a physically grounded framework to infer mixed layer depth (MLD) and vertical heat flux from surface-observable variables.

2 Key characteristics of submesoscale eddies in the Icelandic Basin

To demonstrate the applicability of the developed method, we select the Icelandic Basin as the test region, where previous observations indicate pronounced submesoscale activity, particularly during the spring restratification period (Johnson et al., 2016; Mahadevan et al., 2012). We use output from LLC4320, a $1/48^\circ$ global ocean-sea ice simulation based on the MIT General Circulation Model (Marshall, Adcroft, et al., 1997; Marshall, Hill, et al., 1997), which has been widely used to investigate submesoscale dynamics (Su et al., 2018; Siegelman, 2020; Khatri et al., 2021). The model has vertical resolution ranging from 1.0 m to 41.5 m in the upper 800 m, and mean horizontal spacing of 1.13 km in the selected region. For details of the model configuration, we refer the reader to Gallmeier et al. (2023).

Fig. 1(a) shows the location of the domain. From late November to early March, a strong net surface buoyancy flux, dominated by surface cooling, drives deepening of the ML base (Fig. 1b). During spring (March to May), the ML re-stratifies, as indicated by shoaling of the ML and increased ML stratification. In summer, surface heating maintains a shallow ML throughout the season. Fig. 1(c)–(h) show the surface vorticity ζ , strain rate σ , and horizontal divergence Δ , which are commonly used to quantify the intensity of submesoscale motions (Balwada et al., 2021), where

$$\zeta = v_x^s - u_y^s, \quad \sigma = \sqrt{(u_x^s - v_y^s)^2 + (v_x^s + u_y^s)^2}, \quad \Delta = u_x^s + v_y^s, \quad (1)$$

the superscripts \cdot^s denote surface fields, and the subscripts represent partial derivatives. Each field is normalized by the domain-averaged Coriolis parameter $f_0 = 1.27 \times 10^{-4} \text{ s}^{-1}$. Surface eddy activity exhibits strong seasonality in this region, with pronounced submesoscale activity in winter and spring, and weaker mesoscale eddies during summer and autumn.

Baroclinic instability of submesoscale fronts in the ML generates submesoscale eddies (Boccaletti et al., 2007), which induce overturning circulations that adiabatically slump the fronts (Fox-Kemper et al., 2008), converting horizontal density gradients into vertical stratification. Therefore, the agreement between horizontal and vertical Turner angles can be used to identify periods when frontal slumping by these eddies dominates the ML restratification, as the Turner angles quantify the relative contributions of temperature and salinity to density (Johnson et al., 2016). Assuming a linear equation of state, the potential density can be approximated as

$$\rho = \rho_0 \left[1 - \alpha(\theta - \theta_0) + \beta(S - S_0) \right], \quad (2)$$

where α is the thermal expansion coefficient, β is the haline contraction coefficient, θ_0 is the reference temperature, and S_0 is the reference salinity. Following Johnson et al.

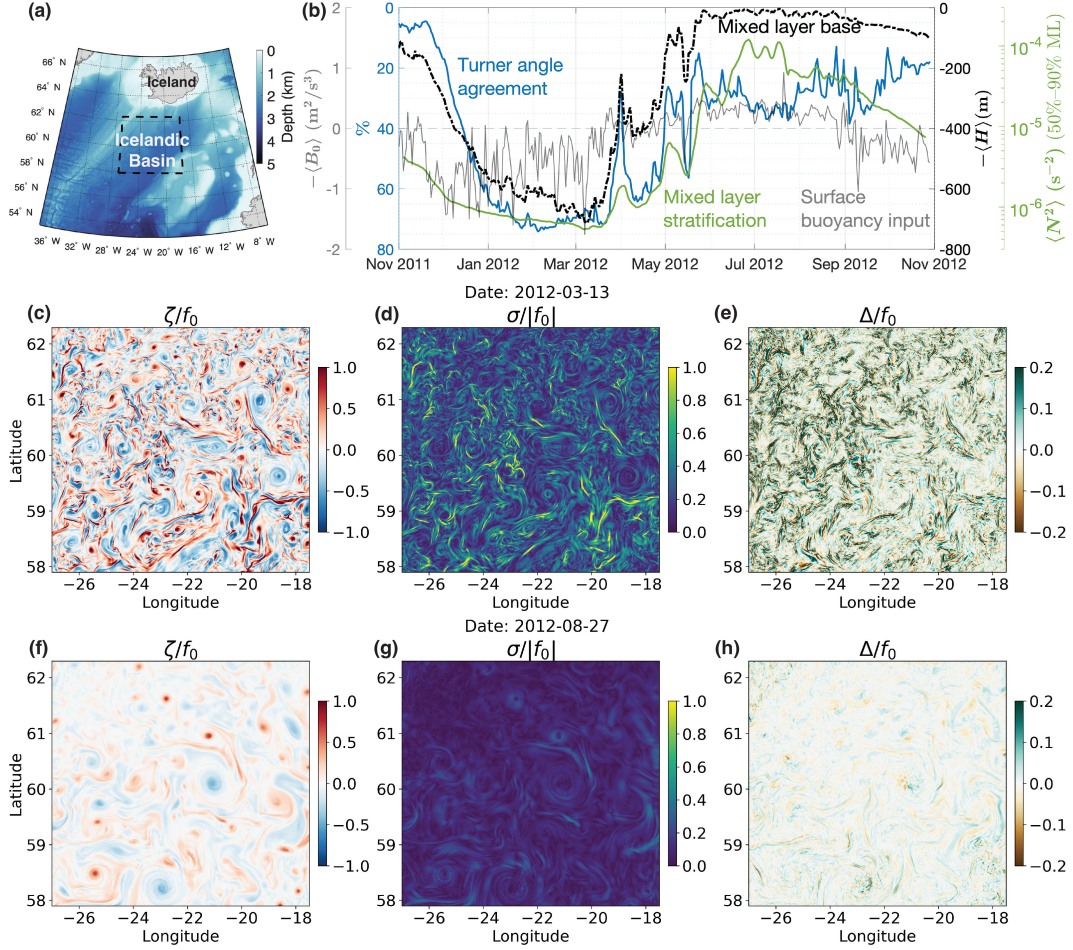

Figure 1. (a) Seafloor bathymetry with the Icelandic Basin highlighted by a black dashed box (27°W – 17.5°W , 57.9°N – 62.3°N). (b) Timeseries of the domain-averaged net surface buoyancy input (gray), vertical position of the ML base (equal to $-\langle H \rangle$) (black), mean stratification averaged over 50%–90% of the MLD (green), and percentage of Turner angle differences less than 10° (blue). (c-h) Daily-averaged surface vorticity, strain rate, and horizontal divergence normalized by the Coriolis parameter, for early spring (c-e; Mar 13th, 2012) and late summer (f-h; Aug 27th, 2012).

110 (2016), we define the horizontal and vertical Turner angles as

$$\text{Tu}_h = \arctan \left[\frac{\alpha \partial_n \theta^s + \beta \partial_n S^s}{\alpha \partial_n \theta^s - \beta \partial_n S^s} \right], \quad \text{Tu}_v = \arctan \left[\frac{\alpha \partial_z \theta + \beta \partial_z S}{\alpha \partial_z \theta - \beta \partial_z S} \right], \quad (3)$$

111 where

$$\partial_n = \frac{\nabla_h \rho}{|\nabla_h \rho|} \cdot \nabla_h \quad (4)$$

112 denotes the horizontal cross-isopycnal gradient, and $\nabla_h = (\partial_x, \partial_y)$ represents the hor-
 113 izontal gradient operator. We quantify the agreement between the horizontal and ver-
 114 tical Turner angles using the percentage of the absolute Turner angle difference less than
 115 10° . As shown in Fig. 1(b), the two Turner angles agree relatively well during winter and
 116 early spring (January–April), indicating the prevalence of submesoscale fronts and sug-
 117 gesting that ML restratification in early spring largely results from frontal slumping, con-
 118 sistent with observations by Johnson et al. (2016).

119 3 Diagnosing mixed layer steric height from submesoscale SSH

120 We hypothesize that ML eddies imprint detectable signatures on SSH at submeso-
 121 scale wavelengths. This hypothesis is motivated by previous findings that vertically
 122 integrating the global *in-situ* density anomaly over the upper 2,000 m of the ocean yields
 123 a steric height estimate that closely tracks variations in SSH (Delman, 2025). Such an
 124 approach primarily captures large-scale circulation and mesoscale eddies, which can ext-
 125 end into the deep ocean. In addition, Wang et al. (2025) show that in the California
 126 current region, the SSH anomaly captured by SWOT, which resolves submesoscale vari-
 127 ability, closely matches the steric height anomaly derived from mooring measurements
 128 in the upper 500 m after removing barometric and barotropic effects (their Fig. 2). Be-
 129 low, we adopt a similar approach but consider only the density variations within the ML.
 130 We examine whether variations in ML steric height can be inferred from SSH anoma-
 131 lies, provided that the contributions from large-scale circulation and mesoscale eddies
 132 are filtered out.

133 We define the MLD as the depth at which the potential density exceeds the sur-
 134 face density by a criterion of $\Delta\rho = 0.03 \text{ kg/m}^3$. By definition, destruction of stratifi-
 135 cation in the mixed layer (*e.g.*, by increased mixing) is inversely related to the deepening
 136 of the mixed layer, *i.e.*,

$$\overline{\partial_z b}^z = \frac{g \Delta\rho}{\rho_0} \frac{1}{H}, \quad (5)$$

137 where $b = -g(\rho - \rho_0)/\rho_0$ is buoyancy, ρ is potential density, $\rho_0 = 1027.5 \text{ kg/m}^3$ is the
 138 reference density, $g = 9.81 \text{ m/s}^2$ is the gravitational acceleration, H is the MLD, and
 139 the overline $\overline{\cdot}^z$ denotes ML averages

$$\overline{\cdot}^z = \frac{1}{H} \int_{-H}^0 \cdot dz. \quad (6)$$

140 This definition of MLD differs slightly from the canonical one (de Boyer Montégut et al.,
 141 2004; Treguer et al., 2023), which uses 10 m depth as a reference level to reduce the in-
 142 fluence of diurnal warming/cooling on MLD estimates. After removing the diurnal cycle
 143 by taking daily averages, we find that the two definitions produce nearly identical domain-
 144 averaged MLD (Fig. S1). When computing ML averages, we additionally exclude regions
 145 where the MLD is shallower than 10 m in all analysis. Note that, after taking domain
 146 averages, the results are not sensitive to either the definition of the MLD, or the exclu-
 147 sion of regions with $H < 10 \text{ m}$.

148 **3.1 Mixed layer steric height**

149 We define the ML steric height as the vertical integral of the *in-situ* density anomaly
150 over the ML following Eq. 1 of Wang et al. (2025).

$$\eta_{\text{steric}} = -\frac{1}{\rho_0} \int_{-\langle H \rangle}^0 \rho'_{\text{in situ}} dz, \quad (7)$$

151 where the angle brackets $\langle \cdot \rangle$ denote horizontal average over the domain of interest, the
152 *in-situ* density anomaly is defined as the departure from the domain-averaged value

$$\rho'_{\text{in situ}} = \rho_{\text{in situ}} - \langle \rho_{\text{in situ}} \rangle, \quad \langle \cdot \rangle = \frac{1}{L_x L_y} \int_0^{L_x} \int_0^{L_y} \cdot dx dy, \quad (8)$$

153 and L_x and L_y denote the horizontal domain sizes.

154 Fig. 2 shows the SSH anomaly (a) and η_{steric} (b). Because the ML is deeper in the
155 northwest of the domain and shallower in the southeast, integrating density anomalies
156 from the domain-averaged ML base produces higher η_{steric} in the southeast. This, how-
157 ever, does not affect our results, as our analysis focuses on the gradient of η_{steric} , which
158 is dominated by small-scale local density variations. We retain the definition of η_{steric}
159 using the domain-averaged MLD for three reasons: (i) it has negligible impact on the
160 gradient magnitudes, (ii) it yields a simpler form for the ML eddy parameterization us-
161 ing steric height; and (iii) it aligns better with the eddy parameterizations employed in
162 coarse-resolution climate models, where small-scale variations in the MLD are not re-
163 solved.

164 We assume that, once internal waves are temporally filtered out in the daily av-
165 erages, the horizontal gradient of ML steric height is dominated by the variations in tem-
166 perature and salinity, rather than pressure. Under this assumption, the effects of hor-
167 izontal pressure gradients in the ML are small, such that the horizontal gradient of the
168 *in-situ* density $\rho_{\text{in situ}}$ can be approximated by that of the potential density ρ . There-
169 fore, the horizontal gradient of the ML steric height can be approximated as

$$\nabla_h \eta_{\text{steric}} \equiv -\frac{1}{\rho_0} \int_{-\langle H \rangle}^0 \nabla_h \rho'_{\text{in situ}} dz \approx -\frac{1}{\rho_0} \int_{-\langle H \rangle}^0 \nabla_h \rho dz \approx -\frac{1}{\rho_0} \overline{\nabla_h \rho^z} \langle H \rangle = \frac{1}{g} \overline{\nabla_h b^z} \langle H \rangle, \quad (9)$$

170 which shows that $\nabla_h \eta_{\text{steric}}$ scales with the ML-averaged horizontal buoyancy gradient
171 multiplied by the domain-averaged MLD.

172 In the following analysis, we apply a mesoscale filter that effectively removes large-
173 scale pressure anomalies. As a result, our method is likely insensitive to large-scale pres-
174 sure anomalies at depth, even when internal waves cannot be removed through daily av-
175 eraging (*e.g.*, when applied to the SWOT data).

176 **3.2 Submesoscale sea surface height anomaly**

177 In order to isolate the signal associated with submesoscale eddies, we apply a Gaus-
178 sian filter to SSH to remove the large-scale flow, including mesoscale eddies, following
179 Uchida et al. (2022). To account for the seasonal variability of ML eddy scales, this Gaus-
180 sian filter scale is determined by the time-varying wavelength of the most unstable ML-
181 instability mode (Stone, 1970):

$$\lambda_{\text{MLI}} = \frac{2\pi}{\sqrt{5}/2} L_d \sqrt{1 + Ri_b^{-1}}, \quad (10)$$

182 where $L_d = \overline{N^z} H / f$ is the ML radius of deformation, $N = \sqrt{\partial_z b}$ is the buoyancy fre-
183 quency, f is the Coriolis parameter, $Ri_b = \frac{N^2 f^2}{|\overline{\nabla_h b}|^2}{}^{\text{hm}, z}$ is the balanced Richardson
184 number, with $\overline{\cdot}{}^{\text{hm}, z}$ denoting the harmonic mean in the vertical direction to em-
185 phasize the influence of small local Richardson numbers. In this region, λ_{MLI} peaks in

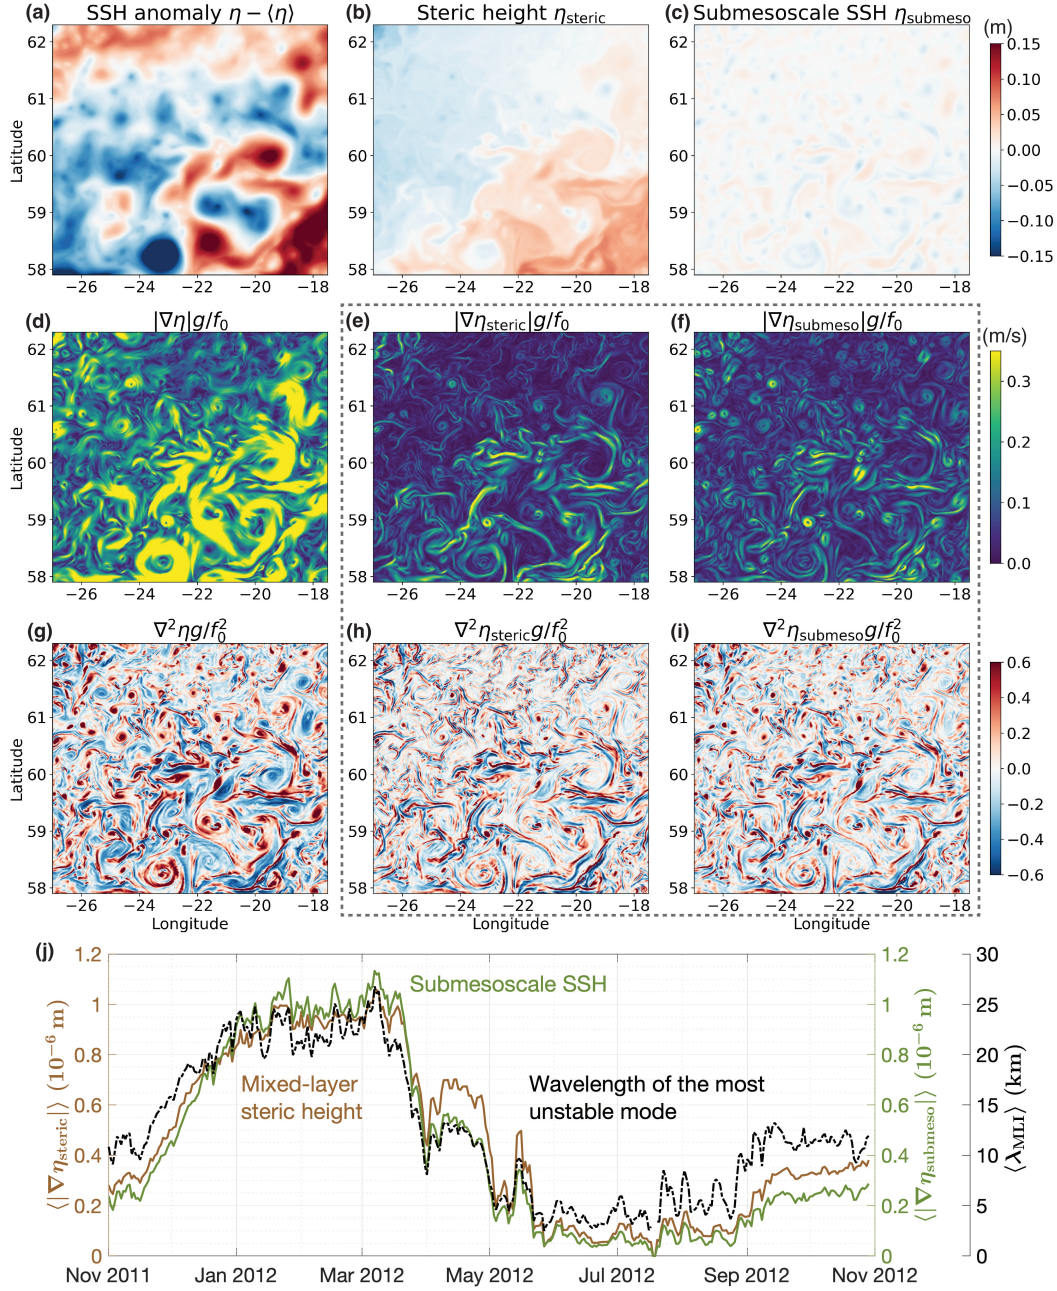

Figure 2. Daily-averaged (a) SSH anomaly, (b) ML steric height, and (c) submesoscale SSH anomaly on Feb 15th, 2012. (d-f): Gradient magnitude of the first row, normalized by f_0/g to obtain the unit of velocity (m/s). (g-i): Laplacian of the first row, normalized by f_0^2/g to obtain the Rossby number (dimensionless). (j) Timeseries of daily- and domain-averaged gradient magnitude of ML steric height (brown) and submesoscale SSH (green), along with the wavelength of the most unstable ML instability mode λ_{MLI} (black).

186 winter and early spring, and reaches its seasonal minimum during summer (Figs. 2j and
187 S2, Text S2), consistent with Dong et al. (2020).

188 We filter the SSH field at the scale $L_{\text{MLI}} = 0.8\langle\lambda_{\text{MLI}}\rangle$ (hereafter referred to as the
189 submesoscale SSH). The factor 0.8 is chosen so that the resulting submesoscale SSH is
190 better aligned with the steric height.

$$\eta_{\text{submeso}}(x, y, t) = \eta'(x, y, t) - \int_0^{L_x} \int_0^{L_y} \eta'(x', y', t) \frac{1}{2\pi\sigma^2} e^{-\frac{(x-x')^2 + (y-y')^2}{2\sigma^2}} dx' dy', \quad (11)$$

191 where $\eta' = \eta - \langle\eta\rangle$ is the SSH anomaly, L_{MLI} is prescribed as the Gaussian full width
192 at half maximum, and $\sigma = L_{\text{MLI}}/(2\sqrt{2\ln 2})$ is the corresponding standard deviation.
193 Fig. 2(b–c) shows some mismatch between submesoscale SSH and ML steric height, arising
194 because the definition of η_{steric} neglects horizontal variations in MLD (Text S1). How-
195 ever, this has negligible impact on the gradients.

196 Fig. 2(c–d) shows that the horizontal gradient of submesoscale SSH closely matches
197 that of the ML steric height:

$$\nabla_h \eta_{\text{submeso}} \approx \nabla_h \eta_{\text{steric}}. \quad (12)$$

198 The results remain robust when a constant filter scale is used for σ in place of the time-
199 varying scale L_{MLI} , particularly during seasons of pronounced submesoscale activity (Fig. S3,
200 Text S3). The Rossby number estimated from submesoscale SSH is also in close agree-
201 ment with that derived from steric height (Fig. 2h–i). Combining Eq. 12 with Eq. 9, we
202 obtain that

$$g\nabla_h \eta_{\text{submeso}} \approx \overline{\nabla_h b^z} \langle H \rangle. \quad (13)$$

203 This relation will be used later to reconstruct the evolution of MLD and estimate ML-
204 averaged vertical heat flux from ocean surface states.

205 4 Estimating mixed layer depth from submesoscale SSH

206 Building on the results of the previous section, we derive a theoretical framework
207 for reconstructing MLD using surface variables.

208 4.1 Volume-averaged potential energy budget

209 Inspired by previous studies (Eq. 14 of Thompson et al. (2016); Eq. 3 of Johnson
210 et al. (2020); Eq. 5 of Fox-Kemper et al. (2008)), we consider a volume-averaged poten-
211 tial energy (PE) budget for the surface ML. We decompose the change of ML potential
212 energy into four contributions: (i) net surface buoyancy flux B_0 , (ii) Ekman buoyancy
213 flux B_{Ek} , (iii) frontal slumping by eddy buoyancy flux B_{eddy} , and (iv) a residual term,
214 including the effects of horizontal advection through the lateral boundaries, turbulent
215 mixing at the ML base, vertical advection by internal gravity waves, frontogenesis and
216 frontolysis, *etc.*

$$\frac{\partial}{\partial t} \text{PE} = \langle B_0 + B_{\text{Ek}} + B_{\text{eddy}} \rangle + \text{Residual}^{\text{PE}}. \quad (14)$$

217 Following Sec. 3 of Fox-Kemper et al. (2008) and applying Eq. 5,

$$\text{PE} \equiv \langle -zb^z \rangle \propto \langle H \rangle^2 \langle \overline{\partial_z b^z} \rangle \approx \frac{g\Delta\rho}{\rho_0} \langle H \rangle, \quad (15)$$

218 Therefore, the volume-averaged PE budget in Eq. 14 can be expressed as a budget for
219 the MLD:

$$\frac{\partial \langle H \rangle}{\partial t} = \frac{\rho_0}{g\Delta\rho} \langle B_0 + B_{\text{Ek}} + B_{\text{eddy}} \rangle + \text{Residual}, \quad (16)$$

220 which resembles the ML model presented in Johnson et al. (2023) (their Eqs. A1–A2)
221 and Kraus and Turner (1967), but includes an additional term representing the effects
222 of ML eddies.

223

4.2 Net surface buoyancy flux

224

225

Following [Marshall and Schott \(1999\)](#), the net surface buoyancy flux can be written in terms of the net heat and freshwater fluxes:

$$B_0 = -\frac{g\alpha}{\rho_0 C_p} Q_{\text{heat}} - \frac{g\beta S_0}{\rho_0} Q_{\text{fresh}}, \quad (17)$$

226

227

228

229

230

231

232

233

where $C_p = 3995 \text{ J/kg/K}$ is the specific heat capacity, $S_0 = 35.2 \text{ psu}$ is the reference surface salinity, Q_{heat} is the net surface heat flux (Fig. S4b), and Q_{fresh} is the net surface freshwater flux (Fig. S4c). Here, positive B_0 (surface buoyancy loss) corresponds to an increase in the volume-averaged PE or a deepening of the MLD, typically associated with surface cooling ($Q_{\text{heat}} < 0$). Consistent with observations in the Icelandic Basin ([Johnson et al., 2020](#)), the surface buoyancy flux in the LLC4320 in this region is primarily controlled by the surface heat flux, while the effect of the surface freshwater flux is negligible (Fig. S4).

234

4.3 Ekman buoyancy flux

235

236

237

238

Wind stress can generate or destruct ML stratification (Fig. 1 of [Thomas and Ferrari \(2008\)](#)) by the Ekman buoyancy flux, which can be estimated as the product of the Ekman transport and the surface horizontal buoyancy gradient ($\nabla_h b^s$) (*e.g.*, [Thomas et al. \(2013\)](#); [Thompson et al. \(2016\)](#))

$$B_{\text{Ek}} \approx \frac{\vec{\tau} \times \hat{\mathbf{z}}}{\rho_0 f} \cdot \nabla_h b^s \quad (18)$$

239

240

241

242

where $\hat{\mathbf{z}}$ is the upward unit vector, $\vec{\tau} = (\tau^x, \tau^y)$ is the wind stress, and b^s denotes surface buoyancy. In Eq. 18, using the depth-averaged horizontal buoyancy gradient over the ML, rather than the surface buoyancy gradient, yields qualitatively similar results (Text S4).

243

244

245

246

247

248

249

250

251

252

253

254

255

The contribution of the wind to the changes in the ML stratification can be either positive or negative, depending on the relative orientation of the surface winds and submesoscale fronts in the ocean ([Thomas & Lee, 2005](#); [Thomas & Ferrari, 2008](#)). Glider observations suggest that the magnitude of the Ekman buoyancy flux is generally smaller than, but still comparable to, the eddy-induced buoyancy flux (*e.g.*, Fig. 11b of [Thompson et al. \(2016\)](#)). We will show later that when averaged over a broad region containing many fronts with varying orientation relative to the winds, the mean Ekman buoyancy flux largely cancels out and becomes much weaker than the net surface buoyancy flux and the eddy buoyancy flux. The resulting domain-mean contribution by Ekman buoyancy flux is positive, indicating that on average, wind stress tends to deepen the ML. Note that, because the model cannot represent coupled air–sea dynamics, the Ekman buoyancy flux might be underestimated owing to the lack of nonlinear air–sea interactions, although current feedback may act to reduce the magnitude of Ekman buoyancy flux ([Wenegrat, 2023](#)).

256

4.4 Eddy vertical buoyancy flux

257

258

259

On average, submesoscale eddies act to re-stratify the ML. This effect is represented by a depth-averaged ML eddy vertical buoyancy flux. Following [Uchida et al. \(2022\)](#), we diagnose the eddy-induced vertical buoyancy flux as

$$B_{\text{eddy}} = -\overline{w'b'^z} \equiv -\overline{(w - \tilde{w})(b - \tilde{b})^z}, \quad (19)$$

260

261

262

263

where $\tilde{\cdot}$ denotes a 30-km lateral Gaussian filter. This filter scale needs to be larger than the most unstable wavelength of ML instability, as energy injection in the mixed layer occurs at larger scales ([Z. Zhang et al., 2025](#)), resulting from ML instability, transitional-layer instability, or mesoscale eddies (Text S5).

264 The change in ML potential energy due to submesoscale eddies can be parameter-
 265 ized as (Eq. 5 of Fox-Kemper et al. (2008); Eqs. 2–4 of Fox-Kemper and Ferrari (2008))

$$\langle -w'b' \rangle \approx -\frac{C_e \mu(z)}{|f|} \langle H \rangle^2 \langle \overline{\nabla_h b^z} \rangle^2 \quad (20)$$

266 where $C_e = 0.06$ is the recommended coefficient value, and $\mu(z)$ is a vertical structure
 267 function that peaks in the interior of the ML and decreases to zero at both the ocean
 268 surface and the base of the ML (Eq. 21 of Fox-Kemper et al. (2008)). To represent the
 269 eddy buoyancy flux averaged over the ML, we compute the ML average of the vertical
 270 structure function,

$$\mu_0 = \overline{\mu(z)^z} = \frac{1}{H} \int_{z=-H}^{z=0} \left[1 - \left(\frac{2z}{H} + 1 \right)^2 \right] \left[1 + \frac{5}{21} \left(\frac{2z}{H} + 1 \right)^2 \right] dz = \frac{44}{63}. \quad (21)$$

271 Taking the ML vertical average of Eq. 20 and Substituting Eq. 9 ($\langle H \rangle \overline{\nabla_h b^z} \approx g \nabla_h \eta_{\text{steric}}$)
 272 into the resulting expression gives

$$\langle B_{\text{eddy}} \rangle \approx \left\langle -\frac{C_e \mu_0 g^2}{|f|} |\nabla_h \eta_{\text{steric}}|^2 \right\rangle \approx \left\langle -\frac{C_e \mu_0 g^2}{|f|} |\nabla_h \eta_{\text{submeso}}|^2 \right\rangle. \quad (22)$$

273 Note that this term is always negative, indicating that eddies always act to decrease the
 274 volume-averaged ML potential energy, or equivalently, to shoal the ML.

275 4.5 Governing equation for mixed layer depth

276 By substituting Eqs. 17, 18, 22 into Eq. 16, we obtain an equation for the evolu-
 277 tion of MLD:

$$\begin{aligned} \frac{\partial}{\partial t} \langle H \rangle &\approx \frac{\rho_0}{g \Delta \rho} \left\langle B_0 + B_{\text{Ek}} - \frac{C_e \mu_0 g^2}{|f|} |\nabla_h \eta_{\text{steric}}|^2 \right\rangle + \text{Residual} \\ &\approx \frac{\rho_0}{g \Delta \rho} \left\langle B_0 + B_{\text{Ek}} - \frac{C_e \mu_0 g^2}{|f|} |\nabla_h \eta_{\text{submeso}}|^2 \right\rangle + \text{Residual} \end{aligned} \quad (23)$$

278 When the residual term is small, this equation allows us to infer the MLD given surface
 279 heat flux, wind stress, and SSH anomaly.

280 The contribution of each term to the change in the domain-averaged MLD is shown
 281 in Fig. 3(a). A positive tendency (black, $\partial_t \langle H \rangle$) indicates ML deepening, whereas a neg-
 282 ative tendency indicates ML shoaling. Strong surface cooling acts to deepen the ML from
 283 November to March. Surface wind forcing contributes to ML deepening throughout the
 284 year, but its effect is much weaker than that of surface cooling. The diagnosed eddy-induced
 285 vertical buoyancy flux (VBF) is shown in purple, and the parameterized eddy fluxes by
 286 submesoscale SSH and steric height are shown in green and brown, respectively. Con-
 287 sistent with Eq. 22, the eddy-related terms are always negative, indicating that the ML
 288 eddies always act to shoal the ML.

289 The light pink curve represents the difference between the total tendency and the
 290 terms associated with surface forcing (labeled as the “horizontal” term). It represents
 291 the effects of horizontal eddy restratification and other processes, such as lateral advec-
 292 tion through the domain boundaries. When the eddy-related terms (purple, green, and
 293 brown) align with the pink curve, the residual term is small, indicating that the theo-
 294 retical framework performs well. However, during summer, despite strong surface heat-
 295 ing and very weak eddy restratification, the MLD remains shallow and nearly constant.
 296 This suggests that other processes, such as turbulent mixing and entrainment, may con-
 297 tribute to balance the surface heating. Because our theory is designed for periods when
 298 ML eddies are pronounced, we leave a detailed analysis of the summertime MLD bud-
 299 get to future work.

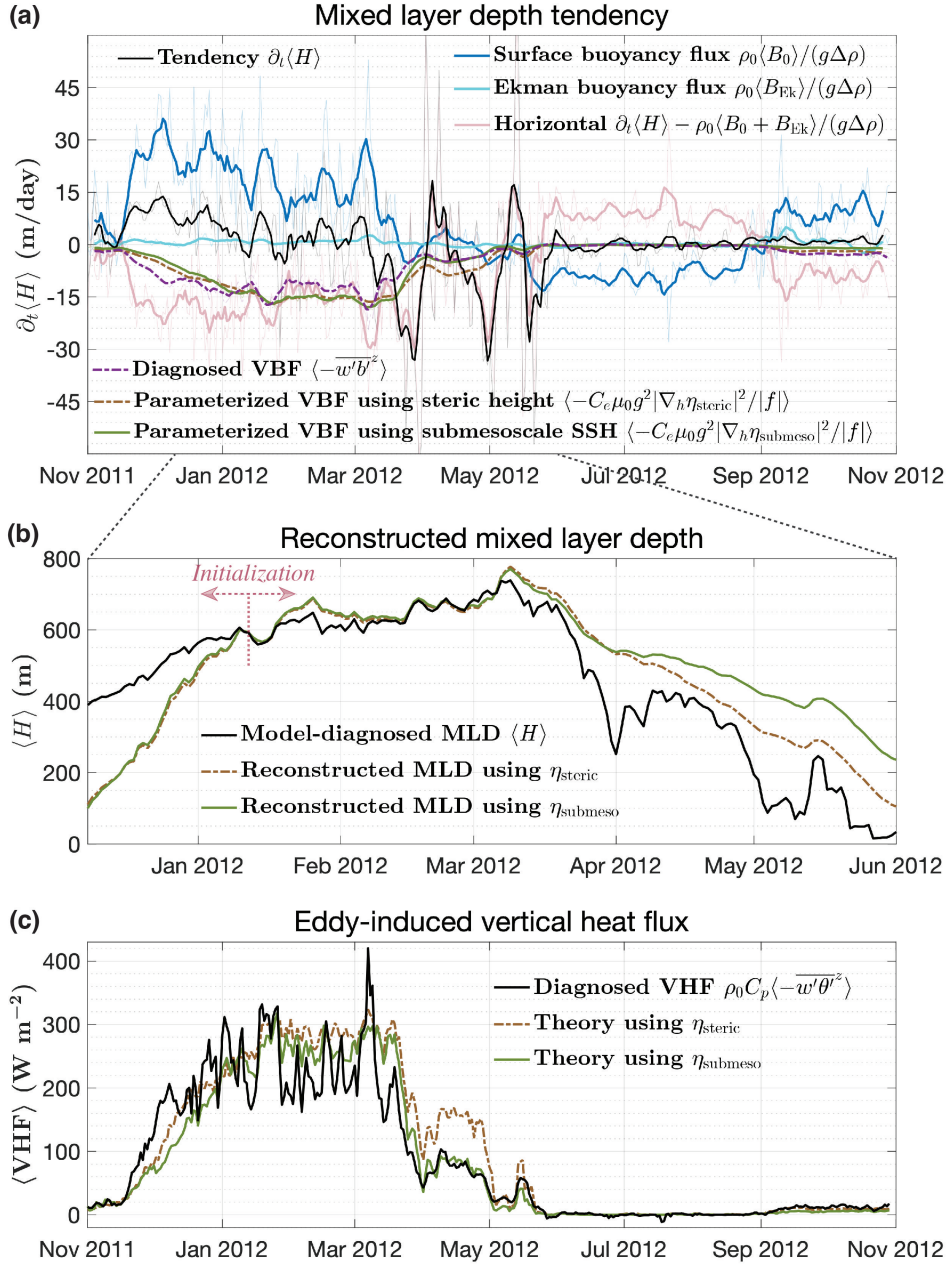

Figure 3. (a) MLD tendency, with thin semi-transparent lines representing daily values and thick lines showing weekly rolling means. (b) Domain-averaged MLD diagnosed from the model compared with the reconstructed MLD derived from ML steric height and submesoscale SSH. The pink dotted line indicates the initialization date (January 12th, 2012), at which the reconstructed MLD is matched to the diagnosed MLD. From this point, the theory-predicted MLD tendency is integrated both forward and backward in time. (c) Timeseries of daily-averaged model-diagnosed and theoretically reconstructed eddy-induced vertical heat flux.

300 Fig. 3 (a) shows that, from January to May, variations in the MLD are primarily
 301 controlled by the competition between surface forcing and ML eddy restratification. This
 302 balance allows us to reconstruct the MLD during this period by integrating Eq. 23 for-
 303 ward and backward in time, from a selected initialization date. Fig. 3 (b) shows the re-
 304 constructed MLD with an initialization date of Jan 12th, 2012. This initialization data
 305 is selected because the horizontal and vertical Turner angles begin to agree well (Fig. 1b),
 306 indicating that eddy activity becomes important in the MLD budget. Although errors
 307 accumulate with time, the difference between the reconstructed and diagnosed MLD re-
 308 mains within 8% (or < 50 m, relative to the MLD exceeding 600 m) for most of the pe-
 309 riod from January through the end of March.

310 Frontogenesis and frontolysis can also influence the MLD. Scaling analysis in [Thomas](#)
 311 [and Ferrari \(2008\)](#) (their Eq. 21) suggests that, typically, the influence of frontogenesis
 312 on the stratification of the surface ML can be on the same order of magnitude as wind
 313 forcing. However, we find that the Ekman buoyancy flux is much smaller than the sur-
 314 face heat flux and eddy buoyancy flux (Fig. 3a), and the contribution of frontogenesis
 315 or frontolysis in LLC4320 is also expected to be small due to insufficient resolution and
 316 the lack of coupled air-sea dynamics.

317 5 Estimating vertical heat flux from submesoscale SSH

318 The effects of ML eddies can be represented by an overturning circulation that acts
 319 to flatten sloping density surfaces, restratifying the ML ([Fox-Kemper et al., 2008](#)). This
 320 circulation transports warm water upward and cold water downward, producing an eddy-
 321 induced vertical heat flux (VHF).

322 In this section, we modify the submesoscale VHF parameterization using the sur-
 323 face density ratio and submesoscale SSH. This approach has potential observational ap-
 324 plications: given satellite-observed surface temperature and salinity, together with sub-
 325 mesoscale SSH from SWOT, the VHF could be estimated.

326 We diagnose the submesoscale eddy-induced VHF following the same approach as
 327 for the vertical buoyancy flux (Eq. 19),

$$\text{VHF}_{\text{diagnosed}} = \rho_0 C_p \overline{w' \theta'^z} = \rho_0 C_p \overline{(w - \tilde{w})(\theta - \tilde{\theta})^z} \quad (24)$$

328 To parameterize the VHF using only surface variables, we use a buoyancy ratio r
 329 to quantify the relative contributions of temperature and salinity to buoyancy, relating
 330 the magnitude of the cross-isopycnal temperature gradient to the buoyancy gradient as

$$\partial_n \theta = r \frac{\partial_n b}{\alpha g}. \quad (25)$$

331 Assuming a linear equation of state $\partial_n b = g(\alpha \partial_n \theta - \beta \partial_n S)$, the buoyancy ratio can
 332 be written as $r = R/(R - 1)$, where $R = \alpha \partial_n \theta / \beta \partial_n S$ is the traditionally defined den-
 333 sity ratio ([Johnson et al., 2020](#)). Both r and R are physically analogous to the horizon-
 334 tal Turner angle (Eq. 3). We use the buoyancy ratio here because it is easier to inter-
 335 pret physically.

336 Following Eqs. 2-3 of [Fox-Kemper and Ferrari \(2008\)](#), the overturning streamfunc-
 337 tion induced by ML eddies is given by

$$\Psi = \frac{C_e \mu(z)}{|f|} H^2 \overline{\partial_n b^z}. \quad (26)$$

338 Below, we compute the submesoscale eddy-induced vertical heat flux using the similar
 339 framework as previous studies (*e.g.*, Eqs. 4-5 of [Spungin et al. \(2025\)](#); Eq. 5 of [Biddle](#)

340 and Swart (2020)), and set the vertical structure function $\mu(z) = \mu_0 = 44/63$ to rep-
 341 resent its mean value throughout the ML (Eq. 21). We additionally substitute the hor-
 342 izontal temperature gradient with the expression given in Eq. 25. The vertical heat flux
 343 is

$$\begin{aligned} \text{VHF}_{\text{MLE}} &= \rho_0 C_p \Psi \overline{\partial_n \theta^z} = \frac{\rho_0 C_p C_e \mu_0}{|f|} H^2 \overline{\partial_n b^z} \overline{\partial_n \theta^z} \\ &= \frac{\rho_0 C_p C_e \mu_0}{\alpha g |f|} H^2 \overline{\partial_n b^z} \overline{r \partial_n b^z} \\ &\approx \frac{\rho_0 C_p C_e \mu_0}{\alpha g |f|} H^2 |\overline{\nabla_h b^z}|^2 r^s \end{aligned} \quad (27)$$

344 Note that, in the equation above, we assume that the buoyancy ratio r remains ap-
 345 proximately constant with depth throughout the ML and can therefore be represented
 346 by its surface value r^s . In addition, we have replaced the squared horizontal cross-isopycnal
 347 buoyancy gradient ($|\partial_n b|^2$) with the squared magnitude of the horizontal buoyancy gra-
 348 dient ($|\nabla_h b|^2$), as they are identical:

$$\partial_n b \equiv \frac{\nabla_h \rho}{|\nabla_h \rho|} \cdot \nabla_h b = \frac{\nabla_h \rho}{|\nabla_h \rho|} \cdot \left(-\frac{g}{\rho_0} \nabla_h \rho\right) = -\frac{g}{\rho_0} |\nabla_h \rho| = -|\nabla_h b|. \quad (28)$$

349 Finally, we substitute the horizontal buoyancy gradient $\overline{\nabla_h b^z}$ by observable sub-
 350 mesoscale SSH gradient ($\nabla_h \eta_{\text{submeso}}$) or the ML steric height gradient ($\nabla_h \eta_{\text{steric}}$), us-
 351 ing Eq. 9 ($\langle H \rangle \overline{\nabla_h b^z} \approx g \nabla_h \eta_{\text{steric}}$) and Eq. 12 ($\nabla_h \eta_{\text{submeso}} \approx \nabla_h \eta_{\text{steric}}$):

$$\begin{aligned} \langle \text{VHF}_{\text{MLE}} \rangle &\approx \frac{\rho_0 C_p C_e \mu_0 g}{\alpha |f|} \langle |\nabla_h \eta_{\text{steric}}|^2 r^s \rangle \\ &\approx \frac{\rho_0 C_p C_e \mu_0 g}{\alpha |f|} \langle |\nabla_h \eta_{\text{submeso}}|^2 r^s \rangle, \end{aligned} \quad (29)$$

352 As the magnitude of the thermal expansion coefficient α depends on temperature,
 353 it shows strong seasonal variability (Fig. S6a). We choose an annual-mean value of $\alpha =$
 354 $1.60 \times 10^{-4} \text{ }^\circ\text{C}^{-1}$. While different choices of α modify the magnitude of the theoret-
 355 ical prediction, the results shown in Fig. 3(c) remain robust (Fig. S7).

356 In principle, Eqs. 27-29 are applicable only in regions and seasons where the hor-
 357 izontal and vertical Turner angles show good agreement. This requirement arises because
 358 a close alignment between Tu_v and Tu_h is necessary for using the surface buoyancy ra-
 359 tio r^s as a proxy for the mean buoyancy ratio throughout the ML (Eqs. 25, 27). Nev-
 360 ertheless, the theory performs well throughout the year (Fig. 3c), likely because the sum-
 361 mertime eddy VBF is too small to produce noticeable errors. Note that tempera-
 362 ture-salinity compensation (Spiro Jaeger & Mahadevan, 2018) does not affect our results, as
 363 it is implicitly included in the buoyancy ratio r .

364 6 Conclusion and discussions

365 In this study, we proposed a theoretical framework to estimate vertical buoyancy
 366 and heat fluxes, as well as to reconstruct the evolution of MLD from the sea surface state.
 367 The gradient magnitude and Laplacian of the ML steric height closely match the spa-
 368 tially filtered SSH anomaly, revealing clear surface imprints of the mixed layer eddies and
 369 fronts. This enables us to parameterize the ML eddy-induced vertical buoyancy and heat
 370 fluxes using submesoscale SSH. Based on the parameterized eddy buoyancy flux, we de-
 371 veloped a theory to reconstruct changes in the MLD from surface variables. The theo-
 372 retical reconstruction of the MLD agree well with model diagnostics during periods with

373 pronounced submesoscale activity. Despite being conducted in different regions and sea-
 374 sons, our estimates of submesoscale vertical fluxes agree well with recent airborne ob-
 375 servations by Torres et al. (2025), which show that submesoscale processes contribute
 376 more than 80% of the vertical heat flux, with values reaching 227 W/m^2 . Our vertical
 377 heat flux estimates also agrees quantitatively with those of Su et al. (2018).

378 Although the theory performs well, several caveats highlight avenues for further
 379 research. Our theory builds on the parameterization of Fox-Kemper et al. (2008), which
 380 does not account for the effects of wind (Mahadevan et al., 2010) or boundary layer tur-
 381 bulence (Bodner et al., 2023) on submesoscale fronts. Because the model lacks coupled
 382 air–sea dynamics, the Ekman buoyancy flux may be underestimated in this study. In ad-
 383 dition, vertical mixing in LLC4320 is parameterized using the K-Profile Parameteriza-
 384 tion (Large et al., 1994), which can contribute to anomalously deep mixed layers in re-
 385 gions of strong open-ocean convection (Sohail et al., 2020), such as the Icelandic Basin
 386 (Text S6, Fig. S8). Moreover, the MLD budget does not include horizontal advection through
 387 lateral boundaries and turbulent mixing at the base of the ML, which may play impor-
 388 tant roles in regions with strong boundary currents and wave breaking. Notably, hor-
 389 izontal advection could potentially be incorporated into this framework by estimating
 390 it from the SSH gradient under the assumption of geostrophic balance.

391 Our method provides a framework for diagnosing subsurface dynamics from sur-
 392 face observations, providing a physically-grounded approach complimentary to the machine-
 393 learning-based inference from SWOT SSH anomalies proposed by Champenois et al. (2026).
 394 Given satellite observations of SSH, surface temperature, salinity, and surface heat flux,
 395 this approach permits an estimate of ML-averaged vertical heat flux and the tendency
 396 of the MLD. Using MLD observations from *in-situ* measurements such as Argo floats as
 397 initial conditions, the MLD can be reconstructed over several months at resolutions higher
 398 than the standard gridded products. It should be noted that our theory is applicable only
 399 during seasons with pronounced ML eddy activity. In addition, the theory is intended
 400 for horizontally averaged quantities; applying it at individual points can lead to devi-
 401 ations. The present analysis focuses on springtime restratification, and future work will
 402 be needed to evaluate the theory across different forcing regimes.

403 Data and Code Availability

404 The code and data used in this manuscript are available at [https://github.com/bodner-](https://github.com/bodner-research-group/surface_submesoscale)
 405 [research-group/surface_submesoscale](https://github.com/bodner-research-group/surface_submesoscale). The bathymetric data used in Fig. 1(a) comes from
 406 ETOPO (2022).

407 Conflict of Interest declaration

408 The authors declare there are no conflicts of interest for this manuscript.

409 Acknowledgments

410 This work was supported by NASA award number 80NSSC24K1664. We acknowledge
 411 the MIT Office of Research Computing and Data for providing high performance com-
 412 puting and data storage resources. We thank Dimitris Menemenlis and Hector Torres
 413 for making LLC4320 model output available. We sincerely appreciate Tatsu Monkman
 414 for helpful guidance on accessing the LLC4320 dataset. We also thank Jinbo Wang, Spencer
 415 Jones, Dhruv Balwada, and Shafer Smith for valuable discussions.

6 **Contents of this file**

7 1. Text S1 to S6

8 2. Figures S1 to S8

9 **Text S1. Mixed-layer steric height**

10 In the main manuscript, we define the mixed-layer steric height as the *in situ* density
 11 anomaly integrated vertically from the domain-averaged mixed-layer base, $-\langle H \rangle$, to the
 12 sea surface (Eq. 7). The discrepancies between the mixed-layer steric height and sub-
 13 mesoscale SSH shown in Fig. 2b–c result from this definition, as the mixed layer depth
 14 varies substantially within the selected domain.

15 If instead the integration is performed from the local mixed layer depth, $H(x, y, t)$, *i.e.*,

$$\eta_{\text{steric}} = -\frac{1}{\rho_0} \int_{-H}^0 \rho'_{\text{in situ}} dz,$$

16 in Eq. 9, the Leibniz integral rule must be applied when computing the horizontal gradient
 17 of η_{steric} to account for spatial variations in the mixed layer depth:

$$\nabla_h \eta_{\text{steric}} = -\frac{1}{\rho_0} \int_{-H}^0 \nabla_h \rho'_{\text{in situ}} dz - \frac{1}{\rho_0} \rho'_{\text{in situ}} \Big|_{z=-H} \nabla_h H.$$

18 The last term may complicate the mixed-layer eddy parameterizations based on steric
 19 height and submesoscale SSH, although it is likely small because $\nabla_h \eta_{\text{steric}}$ in the equation
 20 above is primarily controlled by local horizontal density gradients rather than by large-
 21 scale variations in the mixed layer depth.

22 **Text S2. Seasonality of the most unstable mixed layer instability wavelength**

23 In the Icelandic Basin, the wavelength of the most unstable mixed-layer instability mode
 24 λ_{MLI} peaks in winter and early spring, and reaches its seasonal minimum during summer
 25 (Fig. S2a). This seasonal cycle can be understood as follows:

Given the definition of the mixed layer depth in Eq. 5 of the main text ($\overline{N^{2z}} = g\Delta\rho/(\rho_0 H)$), λ_{MLI} can be approximated as

$$\begin{aligned}\lambda_{\text{MLI}} &= \frac{2\pi}{\sqrt{5/2}} L_d \sqrt{1 + Ri_b^{-1}} \\ &= \frac{2\pi}{\sqrt{5/2}} \frac{\overline{N^z} H}{f} \sqrt{1 + \left(\overline{N^2 f^2 / |\nabla_h b|^2}^{\text{hm}, z} \right)^{-1}} \\ &\approx \frac{2\pi}{\sqrt{5/2} f} \sqrt{\overline{N^{2z}} H^2 + \frac{|\overline{\nabla_h b}|^{2z}}{f^2} H^2} \\ &= \frac{2\pi}{\sqrt{5/2} f} \sqrt{\frac{g\Delta\rho}{\rho_0} H + \frac{|\overline{\nabla_h b}|^{2z}}{f^2} H^2}\end{aligned}$$

indicating that it is largely controlled by the mixed layer depth H (Fig. S2).

Text S3. Sensitivity of submesoscale SSH to filter size

In the main manuscript we adopt a time-dependent filter for submesoscale SSH (Eq. 11) to account for the seasonal variability in eddy size. Here, we test the sensitivity of submesoscale SSH to the choice of filter size. We reproduce Figs. 2(j), 3(b), and 3(c) of the main manuscript using a constant Gaussian filter instead of the time-varying filter, with the filter size (Gaussian full width at half maximum) set to 17 km.

From January to late March, when the horizontal and vertical Turner angles agree well, the theory reliably reconstructs the mixed layer depth and vertical heat flux with a constant filter (Fig. S3). This suggests that during periods with strong submesoscale activity, the method is relatively insensitive to the choice of filter.

From April to September, the constant filter size exceeds the most unstable mixed layer instability wavelength. As a result, the gradient magnitude of submesoscale SSH is overestimated (Fig. S3a), leading to overestimation of the eddy-induced vertical heat

42 flux (Fig. S3c) and excessively rapid shoaling of the reconstructed mixed layer depth
 43 (Fig. S3b).

44 **Text S4. Ekman buoyancy flux**

45 In principle, the horizontal buoyancy gradient averaged over the Ekman layer should
 46 be used to estimate the Ekman buoyancy flux. However, because the Ekman layer depth
 47 cannot be diagnosed without the knowledge of the vertical eddy viscosity in the K-profile
 48 parameterization (KPP), we instead use the surface buoyancy gradient as an approxima-
 49 tion in Section 4.3 of the main manuscript. This approximation has been widely used in
 50 previous studies (*e.g.*, Zheng et al., 2025; Wenegrat, 2023).

51 **Text S5. Eddy-induced vertical buoyancy flux**

52 In Section 4.4 of the main manuscript, we define the eddy-induced vertical buoyancy
 53 flux (VBF) as

$$B_{\text{eddy}} = -\overline{w'b'}^z \equiv -\overline{(w - \tilde{w})(b - \tilde{b})}^z. \quad (1)$$

54 Here, we used a Gaussian filter with a standard deviation of 30 km, which is larger than
 55 the filter applied to the submesoscale SSH. We find that the selected filter scales provide
 56 the best agreement with eddy baroclinic instabilities.

57 Zhang et al. (2025) show that in LLC4320, energy injection in the mixed layer occurs
 58 at scales larger than λ_{MLI} , the most unstable wavelength of mixed-layer instability (their
 59 Figs. 4–5), arising from mixed-layer instability, transitional-layer instability, or mesoscale
 60 eddies. This is consistent with our finding that the filter scale needs to be slightly larger
 61 for the eddy buoyancy flux to account for these additional affects.

Increasing the filter scale incorporates contributions from mesoscale processes, with mesoscale eddies (horizontal scales ranging from 30 km to 60 km) contributing about 13% of the total vertical buoyancy flux (Fig. S5), while scales smaller than 30 km contributing about 87%. This agrees with the airborne observations by Torres et al. (2025), which show that submesoscale processes contribute more than 80% of the vertical heat flux.

Additionally, although the Gaussian filter does not preserve the Reynolds decomposition required for exact buoyancy budget closure, it is adequate for this leading-order analysis, and replacing it with a box filter (horizontal coarse graining) that preserves the Reynolds decomposition yields very similar results.

Text S6. KPP boundary layer depth

In LLC4320, the boundary layer depth in the K-Profile Parameterization (KPP) is defined as the shallowest depth at which the Richardson number reaches a critical threshold of $Ri_c = 0.3559$. The deep KPP boundary layer observed during winter appears to be associated with open-ocean convection driven by strong surface cooling. Large spikes in the KPP boundary layer depth (Fig. S8a) are likely associated with abrupt changes in surface wind stress (Fig. S8b).

The mismatch between the KPP boundary layer depth and the mixed layer depth (pink shading in Fig. S8a) during spring may indicate the presence of springtime eddy restratification, coinciding with the period of good Turner angle agreement (Fig. 1b).
